uvby-β PHOTOMETRY OF OPEN CLUSTERS. IV.
NGC 1444, NGC 1662, NGC 2129, NGC 2169, AND NGC 7209

J.H. Peña and R. Peniche

Instituto de Astronomía
Universidad Nacional Autónoma de México

RESUMEN

Se presenta fotometría uvby-β de los cúmulos abiertos NGC 1444, NGC 1662, NGC 2129, NGC 2169 y NGC 7209. Del análisis de los datos se determina enrojecimiento, temperatura y gravedad para cada estrella y de la distancia y el enrojecimiento de cada una se determina el módulo de distancia y el enrojecimiento del cúmulo. La edad de cada cúmulo se determina por comparación directa con modelos teóricos. Para NGC 2129 no se ha encontrado ninguna acumulación estelar.

ABSTRACT

uvby-β photoelectric photometry of the open clusters NGC 1444, NGC 1662, NGC 2129, NGC 2169, and NGC 7209 is presented. From the analysis of the data reddening, distance, temperature and gravity are determined for each star and, from the distance and reddening of each, reddening and a mean distance modulus to the clusters is assigned. Numerical value of age for each is determined through direct comparison with theoretical models. No star clustering has been found in the direction of NGC 2129.

1. INTRODUCTION

This is the fourth paper of a series (Peniche et al. 990, Peña et al. 1994, Peña et al. 1993; Papers I, I, and III, respectively) which has the purpose of xamining the nature of the stars belonging to open lusters. The aims of this series are, among others: to study short period pulsating stars, mainly of the Scuti type, by first establishing the membership f each star to the cluster, *ii)* to determine the bundance of the Be and Ap phenomena and blue tragglers in open clusters for clusters of different ges and metallicities, and eventually, *iii)* to study he chemical enrichment of the Galaxy when age, ynamics, and metallicity are known for a fair umber of clusters.

In the present study, an analysis of the open clusers NGC 1444, NGC 1662, NGC 2129, NGC 2169, nd NGC 7209 is presented. These clusters were elected because they seem to have a relatively large umber of young stars. This conclusion is supported by the photometric studies in *UBV* presented y Hoag et al. (1961).

2. OBSERVATIONS

The observations were carried out at the Observatorio Astronómico Nacional (OAN) of UNAM. For the acquisition of the photometric data, the 1.5-m telescope at the OAN was used with a multi-channel spectrophotometer that allows the simultaneous observation in the *uvby* filters and in the narrow and wide filters that define Hβ.

The characteristics and procedures of the observations in the 1989 season were presented in Paper II. A total of 25 stars in the direction of the NGC 1444 cluster, 42 in the direction of NGC 1662, 37 in the direction of NGC 2129, 20 in the direction of NGC 2169, and 54 in the direction of NGC 7209 were observed.

3. DATA REDUCTION

The reduction of the photometric data follows the procedure that has been described previously in Paper I. Paper II presented the reduction of the photometric data of the 1989 season to the standard system, the dispersion of the indexes of the ob-

139

served standard stars with respect to the standard star values (Olsen 1983), and the errors due to the star flux measured in each filter as a function of magnitude. The uncertainties were as follows: the coefficients are defined by the equations given in Crawford & Barnes (1970) and in Crawford & Mander (1966). D, F, H, and L are the slope coefficients for $(b-y)$, m_1, c_1, and $H\beta$, respectively; B, J, and I are the color term coefficients of V, m_1, and c_1. The obtained values were: (BDFJHIL) = (0.010, 1.001, 0.940, 0.013, 1.006, 0.078, 1.258). An estimate of the accuracy was determined by comparing the $uvby$-β data with those of Olsen (1983) and Gronbech & Olsen (1977). The average differences, present data minus Olsen's data, were obtained with more than 118 overlapping stars in the $uvby$ and 67 stars in $H\beta$. The obtained mean differences are $(\delta V, \delta(b-y), \delta m_1, \delta c_1, \delta\beta)$ = (0.012, 0.007, 0.011, 0.011, 0.009) mag. The photometric values in the standard system of all the observed stars are presented in Table 1. Column 1 lists a sequential number of the observed stars in decreasing β; column 2, the identification numbers of each star by Hoag et al. (1961). Whenever possible, the nomenclature previously given will be used in the rest of the text and denoted by a prefix H. For those stars that have not been previously observed photometrically, positions were determined from the identification chart of Hoag et al. (1961); columns 8 and 9 list their reported or measured coordinates in their units. In these columns, numbers with two decimal figures are taken directly from the photoelectric and photographic list of Hoag et al. (1961); numbers with only one decimal figure were determined from the chart. The rest of the columns list the photometric values presented. A comparison of the V magnitude for those program stars reported in the present paper which are in common with Hoag et al. (1961) was evaluated along with the relationship $(B-V) - (b-y)$.

4. DISCUSSION

Since the aim of the present paper is to establish hysical and geometrical characteristics of the clus-
:r stars, the first step was to determine membership f the observed stars to each of the clusters. The ıme approach to determine the distance modulus ia Stromgren photometry, as in Paper II, was fol-
ɔwed:

We first defined which stars were main sequence :ars and the broad spectral regions to which they elonged by constructing a $[m_1] - [c_1]$ diagram.

It defines three main spectral regions: early type stars of class B and early A; A and F stars; and late type stars. The distance for each group has been calculated separately.

The calibration of the A and F stars follows a procedure proposed by Nissen (1988) which is based on Crawford's (1975, 1979) calibrations (Paper I); for the B and early A type stars, a method for the determination of the reddening, proposed by Shobbrook (1984) was used as in Paper III.

For the determination of the absolute magnitude

e method proposed by Balona & Shobbrook 984) was employed. The distance modulii and stance were evaluated in the customary ways. ible 2 lists the reddening and unreddened parameters of the member stars in the cluster. Also the isolute magnitude distance modulus and distance 1 pc) are given. Histograms of the distances in irsecs for each cluster were constructed for each oup of stars for which the distances were determined (Figure 1) i.e., B and early A, A and F type irs, as well as for the whole sample. A membership probability has been defined from this histogram by adjusting a Gaussian distribution to it.

The apparent magnitudes of those stars with high probability of membership in the cluster have been represented in a histogram along with the observed stars to infer the range in which the apparent magnitude of the cluster members of B, A and F type stars lie.

To separate binaries from single stars a $\beta - V_0$ diagram of the data presented was constructed for each cluster (Figure 2).
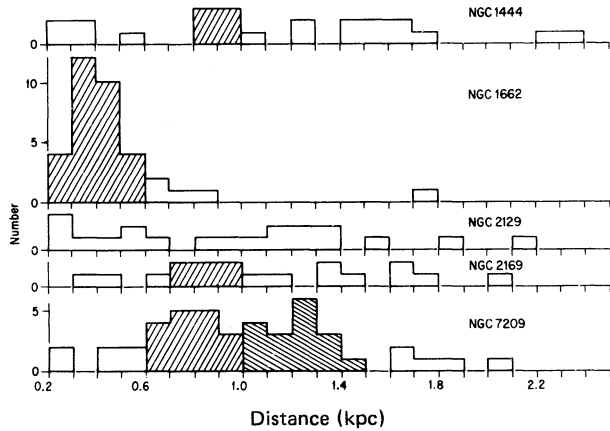

Fig. 1. Histogram of the distances obtained for a) NGC 1444, b) NGC 1662, c) NGC 2129, d) NGC 2169, and e) NGC 7209.

To determine the membership of the cool stars to the cluster, a $(b-y)-V$ diagram was built using only those BAF stars for which a high probability of membership was established. Then, all the cool stars were located on this diagram and those stars that lie in the extension of the previously defined MS into the cooler zone were regarded as stars with a high probability of membership (Figure 3).

In order to estimate the age of the cluster the following procedures were undertaken:

An estimation of the turn-off point was carried out by first determining the temperature and gravity of the member stars, plotting them in the $(m_1 - c_1)$ theoretical grids of Relyea & Kurucz (1978). Second, their $\log L/L_\odot$ were determined from the M_v values reported and the bolometric corrections taken from Lang (1991). With these values and an average metallicity value characteristic of these clusters, [Fe/H] = 0.0, a direct comparison was made with the theoretical models of Meynet, Mermilliod, & Maeder (1993) which take into account mass loss and moderate overshooting and that used recent mean opacities.

An alternative procedure for verifying the temperature of the B stars was followed from the calibration between $[u-b]$ and θ_e. We have followed Pérez et al. (1989) who used the calibrations of Philip & Newell (1975) who define four linear segments over the entire $[u-b]$ range.

The determination of the Ap abundance was carried out through $uvby$-β photometry since it is well-known that the Ap stars lie in a specifically defined zone in the $[m_1] - [c_1]$ diagram. In these zones the Ap Sr-Cr-Eu and Sr-Cr stars are clearly marked.

The uncertainties of each reported figure were evaluated in the following manner: the main source of error consisted in the residuals of the standard

stars observed with respect to the standard index values. To determine the uncertainties of the m_0 c_0 values, i.e., to determine the temperature limit: of the stars, propagation of errors through the standard definitions were done, and the obtained results are of 0.014 and of 0.015 for m_0 and c_0, re spectively.

5. RESULTS

The application of the previously described tech niques to the observations yielded the following re sults for each cluster:

5.1. NGC 1662

The $[m_1] - [c_1]$ diagram gave the following num ber of stars that belong to each range of spectra types: 15 B and early A, 8 A and 3 F stars The distance was determined for each star and it: histogram constructed and shown in Figure 1. I can be immediately seen that there is a conspicuou: clustering of early type stars and that the cluste: must lie in the distance range 250 to 550 pc with a mean value of 381 ± 110 pc. The probabili ty of membership was evaluated considering thes< limits. The histogram of the apparent magnitude: indicates that, in order to reach the stars of late: spectral types, stars fainter than magnitude 1: should be observed. A mean value of $E(b-y)$ equa to 0.231 ± 0.034 has been found.

The binaries have been determined from the β V_0 diagram and four have been found: H25, 22, 33 and 36, although only two, H25 and 33, are cluste members.

The cool stars with a high probability of belong ing to the cluster have been determined from the H R diagram. The four cool stars assumed to belon; to the cluster are: 34, 35, 37, and 42. Two are of th< giant class: H1 and H2, the first of which appears a binary in the ADS catalogue. A confirmation of thi was given by Tiangxing, Kenneth, & Bania (1989)

The temperatures were derived from the m_1 c_1 diagram of Relyea & Kurucz (1978). Accurat< numerical values were obtained from the $[u-b] - \theta$ calibration described by Pérez et al. (1989).

Both methods yield equal star temperature: The estimated age is of 4.86×10^8 yr in agreemen with that reported by Lang (1991). However, due t< the large uncertainty in the temperature range, th age is within the range 3.2 to 6.3×10^8 years. Th uncertainty due to the magnitude was negligible.

The number of Ap stars in the direction c NGC 1662 is high: six, all of which are cluster men bers. One of these H4, had been previously r< ported as A1p Sr-Cr by Young & Martin (1973 Another non-member star, H6, has been reporte as peculiar in a study by Renson (1988).
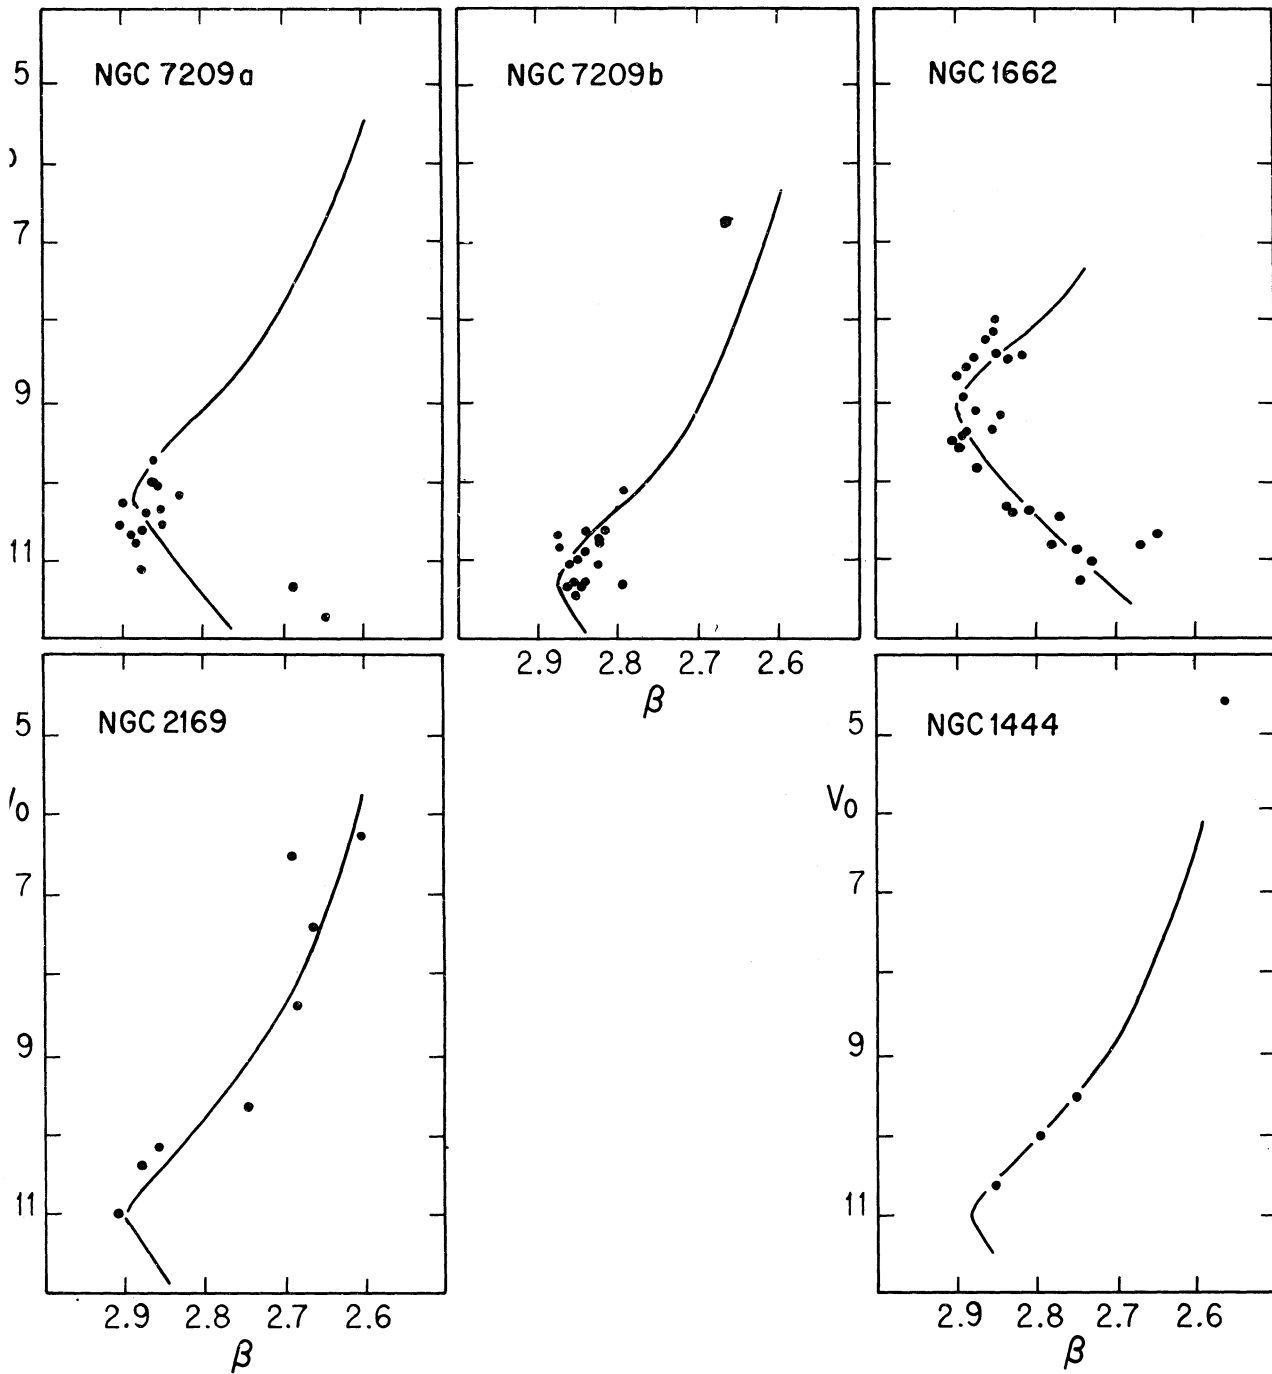

ig. 2. $\beta - V_0$ diagram of the B, A and F stars established as cluster members for the clusters considered. Those stars above ie main sequence were regarded as binaries. The continuous line delineates the main sequence from the photometric alibration by Crawford (1978).

5.2. NGC 1444

The $[m_1] - [c_1]$ diagram shows very few MS tars, with most of them in the early stages. How-ver, the distances determined show a large spread hat can hardly be interpreted as representing a ensely populated cluster. Only six stars, H1,

H8, H12, 8, 10, and 11 were found in a close distance range centered at 906 ± 29 pc with an $E(b-y)$ = 0.540 ± 0.067. One binary has been detected from the $\beta - V_0$ diagram which shows all stars to be in the early type branch.

The position of the six stars in the diagram of
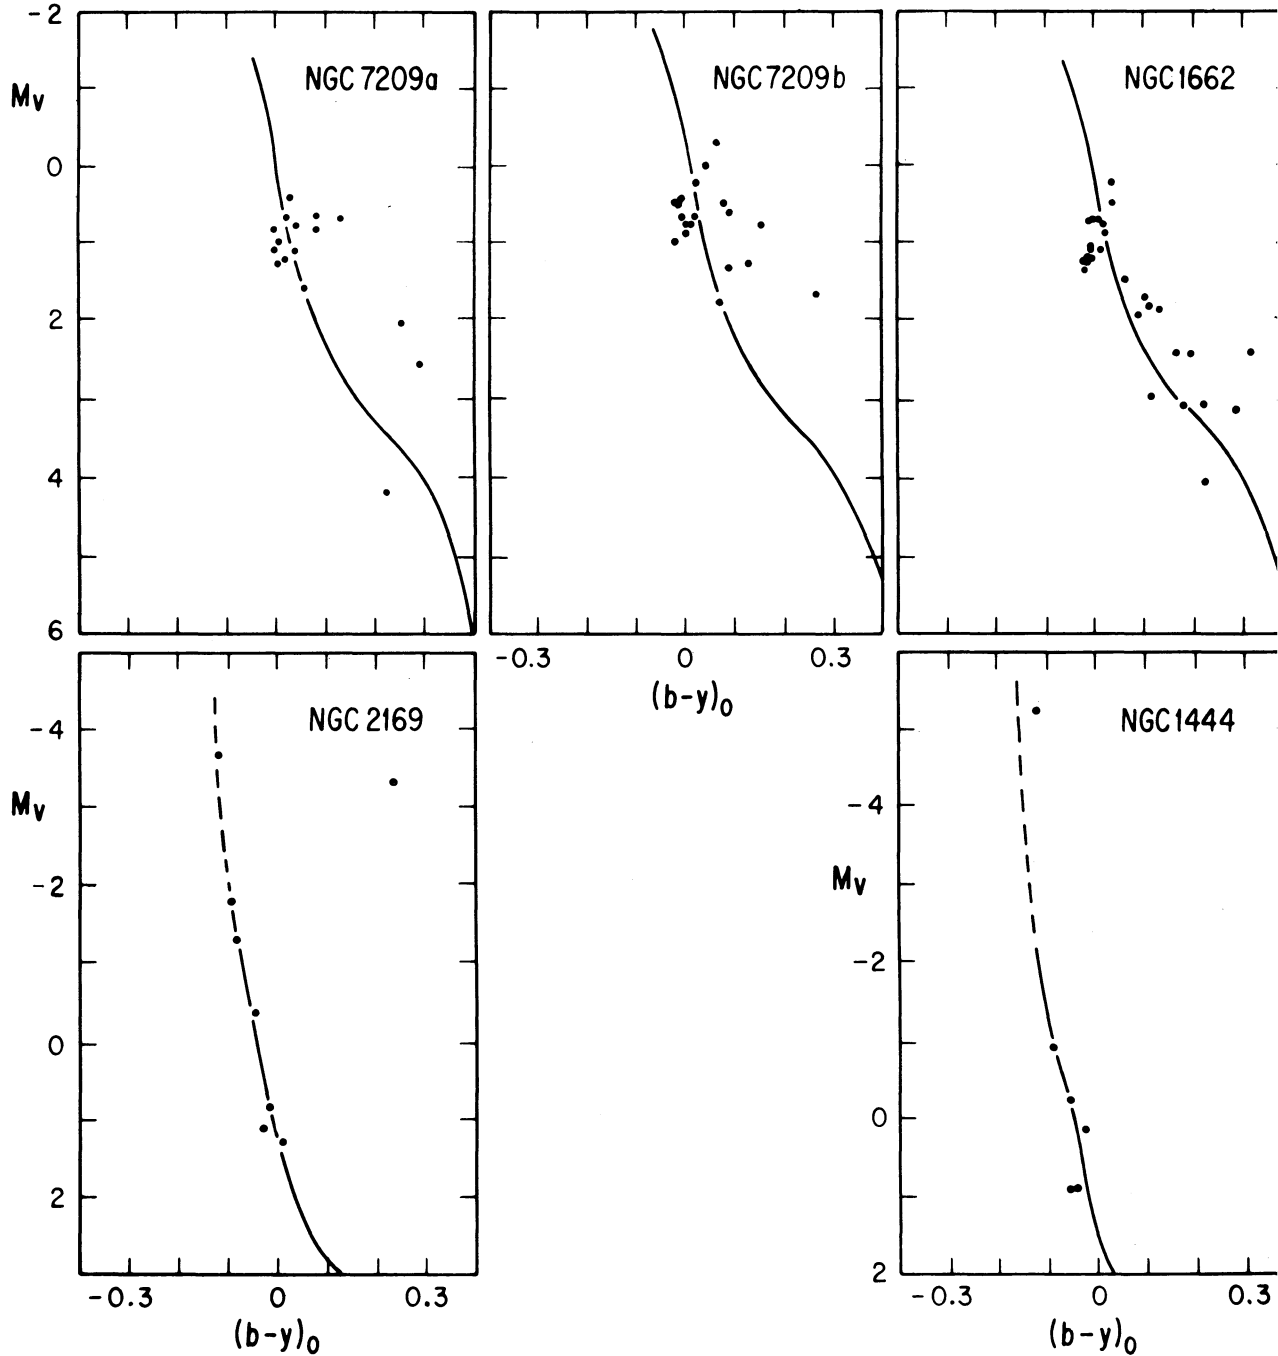

Fig. 3. H-R diagrams of the B, A, and F stars that have been regarded as members of each cluster.

Relyea & Kurucz (1978) shows that they are hot stars, H1 being the hottest. The age of the cluster has been found to be 1.7×10^8 yr in the range 1.0 and 2.0×10^8 yr if the temperature limits are not taken from this latter star. This star, H1, al-though within the distance limits determined for th cluster, is much brighter and hotter and would giv an age of 12×10^6 yr; this makes it a blue straggl candidate. It has been listed as 2783AB in the AD catalogue.

Only one Ap star, 16, from the entire sample observed in the direction of NGC 1444 lies in the box that defines the Sr-Cr-Eu peculiarity, but it does not belong to the cluster.

5.3. NGC 2169

A comparison of the reduced data with the published values of Perry, Lee, & Barnes (1978) was done in order to verify the quality of the observations. Out of thirteen stars observed in common, the standard deviations of the differences in the photometry were of $\Delta(b-y)$, m_1, c_1) of (0.009, .019, 0.019) and two more, H7 and H17 showed anomalously large differences that might be due to the fact that they are cool giants and, hence, likely to suffer significant changes in long periods of time.

A large percentage of the observed stars in the direction of NGC 2169 lie in the $[m_1] - [c_1]$ diagram in the early type stars branch and the distance determined for each one, shown in a histogram, indicates that eight stars belong to the cluster at a distance of 858 ± 128 pc with $E(b-y) = 0.182 ± 0.0103$ and none of them are binaries (Table 2), although H2 and H6 have been reported as spectroscopic binaries by Perry et al. (1978) and Tiangxing et al. 1989), respectively.

The H-R diagram indicates that from the observed MS cool stars none could belong to the cluster and that there are two giants, H3 and H8 that might belong to the cluster. The temperature of the member stars has been determined from their positions in the diagram of Relyea & Kurucz (1978), indicating that this is indeed a young cluster. Its age, from the models of Meynet et al. (1990) is centered at 5.0×10^7 yr within the limits of 3.2 and .3 × 10^7 yr. This numerical value was evaluated without considering star H1, the hottest star which, although within the distance limits of the cluster, seems to be as in the case of H1 in NGC 1444, a blue straggler listed as 4728AB in the ADS catalogue. Only one Ap star, H21, was found in the direction of NGC 2169, but it does not belong to the cluster. Another star, H12, has been reported as an Ap star by Young & Martin (1973) but, again, it does not belong to the cluster. However, due to the relative faintness of the observed stars very few of the A and F stars were included and, hence, very little can be concluded with respect to the Ap phenomenon in this cluster.

5.4. NGC 2129

Although a fair number of bright stars were observed in the direction of NGC 2129 (Table 1) and the $[m_1] - [c_1]$ diagram shows that there are several early type stars as well as several late type MS stars, the determined distance represented in the histogram, Figure 1, does not show the presence of a clustering of stars, raising doubts on its existence. A small inconspicuous clustering of six stars has been found at a distance of 1200 pc, very far from the assumed value of 2000 pc (Lang 1991). No further analysis was carried out, except that one Ap star, H12, has been found in its direction.

5.5. NGC 7209

The $[m_1] - [c_1]$ diagram indicates that the majority of the stars belong to the early type A class, with a few F type stars. The distances were obtained and the histogram constructed. The stars are distributed with two peaks at distance ranges 550 and 950 pc and 950 and 1400 pc respectively, suggesting the existence of two clusters. If only one cluster is assumed, then it would have unreasonable physical limits. Hence, two clusters, NGC 7209a and b are assumed to exist. A mean interstellar extinction $E(b-y)$ was evaluated for each cluster and numerical values of 0.108 ± 0.062 and 0.122 ± 0.066 were obtained for a and b, respectively and at distances of 764 ± 108 and 1194 ± 130 pc. This is consistent with the determined distances since a larger extinction value is obtained for the more distant cluster. Several binaries were detected from the $\beta - V_0$ diagram but only one, 35, belongs to NGC 7209b. With respect to the Ap stars, seven stars are within the limits that define the peculiarities but only one has been determined to be a member of NGC 7209a, whereas there are two in the other cluster.

The hottest stars for both clusters give basically the same temperature of $T_{eff} = 9750$ and 9400 K for a and b, respectively, although the first one has only one star which is located at a position of much hotter temperature, T_{eff} of 14 000 K. The determination of the cool stars was not carried out since it would be impossible to distinguish from the method employed to which cluster they would belong. The age for each cluster was estimated as 5.0×10^8 yr with limits between 4.0×10^8 yr and 6.3×10^8 yr for NGC 7209a and of 7.1×10^8 yr with uncertainties within the range 5.0×10^8 yr and 7.9×10^8 yr for NGC 7209b.

6. CONCLUSIONS

We have presented the results obtained for five young open clusters having a fair number of observed stars with high quality intermediate band photometry (see Table 3). We have also drawn several conclusions with regard to the number of Ap stars that lie in the direction of each cluster, as well as to the number of early type stars and blue stragglers. However, before assuming such values as definitive we must convince ourselves that the sampling of stars is complete enough to draw these statistical conclusions.

PEÑA & PENICHE

NGC 7209b	0.34	0.14	0.12	0.02	0.06	0.10

In retrospect, this being the fourth paper in a series, a more careful procedure was undertaken to select the stars to be observed. Concentric circles were drawn on the identification charts of Hoag et al. (1961). Starting from this origin, we observe only the brightest stars in each circle assuring us that the sample is complete. Hence we are certain that the majority of the brightest stars in the direction of each cluster were observed. Furthermore, after the analysis a direct comparison of the observed stars with the lists for each cluster provided by Hoag et al. (1961) was carried out. The list of stars in the intersection of each set are provided in columns 1 and 2 of Table 1. Later, we examined which of those stars in Hoag et al. (1961) were bluer than $B-V < 0.6$, i.e., those stars that were candidates for either belonging to the spectral class B, or that might belong to the δ Scuti class or be Ap stars. Those that do not belong to the intersection, that is, that were not observed in the present work, were carefully analyzed. For each cluster the following was found:

NGC 1444. In this paper we present observations of 25 stars, whereas Hoag et al. (1961) presented UBV data for 24 stars. The intersection of both sets is constituted by 14 stars and in the complement only one had a $B-V$ low enough so that it could be early enough to be important in the present analysis. However, from its $U-B$ values also reported by Hoag et al. (1961) it can safely be assumed to belong to the giant class.

NGC 1662. Forty two stars were observed in the uvby and 35 in the UVB systems, with an intersection

of 22. Of the remaining, six are earlier than the (class but three are too faint to belong to the cluste

NGC 2129. Thirty seven stars were observed i the uvby system, 29 in the UBV, with 14 intersecting None of the remaining stars in the complement ha a $B-V$ value numerically smaller than the fixed lim of $B-V < 0.6$ mag.

NGC 2169. In this cluster basically all the star (20) in the uvby were observed by Hoag et al. (1961 Their sample consists of 25 stars and there are 1 in the intersection. Six stars of the complemer have $B-V$ in the desired range, but all are too fain Hence they cannot be cluster members.

NGC 7209. This was the most completely ol served cluster since 54 stars were observed. Ther fore, we can be sure that all the early type stars wei observed.

In view of this, the most important results hav been summarized in Table 3 and several conclusior can be drawn:

Reality of Existence. The apparent richness of th clusters vary. Although roughly the same numbe of stars have been observed in each one, the nun ber of member stars varies enormously, from th highest number for NGC 1662 to the lowest possib number, zero, for NGC 2129. For two of the r ported clusters the photometry was not exhaustiv However, in the past, doubts were raised wheth or not both NGC 1444 and NGC 2129 were cluster In particular Lynds (1967) already discussed the e: istence of NGC 1444. Hence, from the results pr sented here and those already mentioned one migl wonder what kind of object one is dealing with.

ems that there is only a small association of early pe stars instead of a densely populated cluster like GC 1662.

On the other hand, with respect to NGC 2129 e decision taken that it is not a cluster was correct nce not much can be said about its existence unless uch fainter stars were to be observed. Furthermore, from the histogram presented one could sily question its existence. Emphasis should be ut on the results of Schmidt-Kaler (1966) about 5 dispersion in absolute magnitude. The same nclusion can be reached inspecting the two color iagram by Hoag et al. (1961). All these results support the findings of the present analysis.

The open cluster NGC 7209 might be a projecon of two clusters at distances of 779 and 1173 pc. he reddening of the more distant one is larger, as xpected.

On discussing the other two clusters one should e aware that NGC 1662, the highly populated uster, is the nearest and oldest. Hence we are oking at a fainter region of the MS whereas for GC 2169, being at a distance double that of GC 1662, only the bright stars are seen. Neverieless, its existence as a cluster is beyond doubt.

Ap Stars. As discussed in Peña et al. (1994), ased on a compilation of the articles of Young & Iartin (1973) and Hartoog (1976) on Ap stars in pen clusters, a ratio of 0.051 for the frequency of p stars in the clusters and of 0.070 for field stars as determined.

From the results obtained in the present paper, higher value is determined for NGC 1662 which ives values of 0.24 and 0.20 for cluster and field, spectively. Better agreement is obtained in the irection of NGC 1444 and NGC 2169 where a ratio f 0.04 and 0.11 is obtained in each case. As was reviously mentioned, no Ap stars members were etected, but that was because we did not reach faint nough magnitudes. NGC 7209 gives, for a and b spectively, a ratio of 0.06 and 0.12 and of 0.14 for ll the Ap stars and the whole sample of the BAF ars.

Blue Stragglers. Mermilliod (1982) has compiled n exhaustive work on blue stragglers in young pen clusters. He has found 39 stars lying to the ft of the MS of 75 open clusters younger than the Iyades and conclude that the blue stragglers apear to be a feature common to all open clusters hatever their age may be and that their number icreases with age.

From the results of the present work two blue ragglers have been found, one in NGC 1444 one in IGC 2169 and none in NGC 1662 and NGC 7209. oth stragglers are within the distance limits of the luster and share the same reddening value. Hence, ractically beyond any doubt, one might conclude iat they belong to the cluster. Unfortunately,

no spectroscopy has been done on these objects to determine if they belong, as Mermilliod (1976) states, to the Be or Of type. Since the blue stragglers found belong to the early type, either careful $uvby$-β photometric calibrations have to be developed to be able to detect their peculiarities or spectra should be taken to detect such anomalies.

Metallicity. In his work Nissen (1988) established a prescription to determine the [Fe/H] index for F type stars. This technique has been followed here. Unfortunately, as has been previously stated and can be seen from the Table 2, only NGC 1662 has enough F type stars belonging to the cluster to evaluate this index. The determined value is characteristic of clusters of its age and distance.

Future Work. We will try to carry out and encourage the following: *i)* Differential photoelectric photometry to detect small amplitude, fast changes encountered in the δ Scuti or B type stars for those stars that belong to the cluster and that are within the spectral limits of such variables. *ii)* Spectroscopic studies in the B type stars to detect any anomalies such as those presented by the Be stars. Also, spectroscopic confirmation of the Ap stars determined here is desirable. *iii)* Absolute multicolor photometry to delineate the lower region of the MS for those cluster of which only the upper part of the MS was observed is needed. In this case, CCD observations that provide larger and deeper samples might be useful to delineate where the cluster is. The membership probability might be reinforced by alternative means like proper motions or radial velocities.
