UNVEILING THE HOT MOLECULAR CORE IN THE ULTRACOMPACT 
H II REGION WITH EXTENDED EMISSION G12.21–0.10

ABSTRACT

We present a multiwavelength study of the cometary H II region G12.21–0.10 using the VLA and OVRO. Both radio continuum (0.3, 0.7, 2 and 3.6 cm) and spectral lines of H\(^4\)\(1\alpha\), \(^{13}\text{CS}(2–1) \& (1–0)\), and \(\text{NH}_3(2,2) \& (4,4)\) observations are included. We find two 3 mm continuum peaks toward G12.21–0.10; one of them is spatially coincident with the UC H II region, while the other coincides spatially with a molecular clump. We also find that the 0.7, 2 and 3.6 cm continuum and H\(^4\)\(1\alpha\) line are only detected toward the UC H II region, while the \(^{13}\text{CS},\) and \(\text{NH}_3\) are spatially associated with the molecular clump. Based on the morphology, kinetic temperature (\(\approx 86\) K), volumetric density (\(\approx 1.5\times 10^6\) cm\(^{-3}\)) and linear size (\(\approx 0.22\) pc) of the molecular clump, we suggest this source is consistent with a hot molecular core.

Key Words: ISM: clouds — ISM: molecules — molecular processes — radio continuum: ISM — radio lines: ISM — stars: formation

1. INTRODUCTION

Hot molecular cores (HMCs) are considered to be the birthplace of high–mass stars (e.g., Kurtz et al. 2000; Garay & Lizano 1999). Thus, to study their physical properties, dynamics, and evolution is crucial for advancing our understanding of high–mass star formation. HMCs are detected mainly by emission of high–excitation molecular lines (e.g., CH\(_3\)CN and \(\text{NH}_3\)) and by millimeter continuum emission from warm dust. A detailed overview of star formation was presented by Stahler & Palla (2005), while a review of high–mass star formation was published by Zinnecker & Yorke (2007).

Water maser emission is a common phenomenon in the neighborhood of newly-formed high–mass stars (e.g., Codella et al. 2004; Trinidad et al. 2003; Hofner & Churchwell 1996). However, the relationship of the \(\text{H}_2\text{O}\) masers to the star formation envi-
and formation of water and methanol masers and for understanding their relation to molecular gas and high-mass star formation.

In § 2 we describe the radio continuum and spectral line observations and data reduction. In § 3 we present the observational results and analysis as follows: 1. We show that the $^{13}$CS (1–0 and 2–1) transitions trace the hot and optically thin dust clump in G12; 2. We calculate the physical characteristics of this clump using NH$_3$ data to confirm that it is a hot molecular core. In § 4 we discuss the $^{13}$CS and NH$_3$ data in the context of the HMC interpretation. A summary is presented in § 5.

2. OBSERVATIONS AND DATA REDUCTION

2.1. Owens Valley Radio Observatory (OVRO) Observations

The $^{13}$CS(2–1) and H$^{1}$α line observations were made with OVRO during March and April 1996. The equatorial and high resolution configurations were used, providing baselines from 30 to 240 m. Cryogenically cooled SIS receivers provided typical SSB system temperatures of 220–350 K. The digital correlator was split into two bands to observe the $^{13}$CS(2–1) ($v_0 =$ 92.49340 GHz) and H$^{1}$α ($v_0 =$ 92.03445 GHz) lines with 30 MHz ($\approx$100 km s$^{-1}$) and 60 MHz ($\approx$200 km s$^{-1}$) bandwidths, and 62 and 60 Hanning-smoothed channels, respectively. This configuration gives a spectral resolution of 0.5 MHz (1.6 km s$^{-1}$) for the $^{13}$CS(2–1) line and 1 MHz (3.3 km s$^{-1}$) for the H$^{1}$α line.

In addition, simultaneous continuum observations at 3 mm were made using a 1 GHz bandwidth analog correlator. The quasars NRAO 530, 3C 454.3, B1908–202, and B1749+096 were observed to track amplitude and phase variations. The bandpass calibration and flux scale were established by observing 3C 273. The absolute flux uncertainty was estimated to be $\approx$20%, and the initial calibration was carried out using the Caltech MMA data reduction package (Scoville et al. 1993). Further data reduction and mapping were done with the AIPS software package. The continuum obtained from the line–free channels was subtracted from the $^{13}$CS and H$^{1}$α emission lines in the $(u, v)$ plane using the program UVLIN in AIPS. Finally, Gaussian fits to the observed spectra were made with the CLASS software package.

2.2. Karl G. Jansky Very Large Array (VLA) Observations

2.2.1. Radio–Continuum Emission

High angular resolution continuum observations at 0.7, 2, and 3.6 cm toward G12 were made with the
VLA\(^8\) in its CnB configuration on 1996 January 29. Two 50 MHz bands were observed, each one including both right and left circular polarizations. We used a subarray of 12 antennas for 7 mm observations and the remaining 15 antennas were employed for 2 and 3.6 cm observations. The flux and phase calibrators were 3C286 (1.45, 3.40 and 5.23 Jy at 0.7, 2, and 3.6 cm) and B1923+210 (1.0, 1.8 and 1.0 Jy; flux densities measured at 0.7, 2, and 3.6 cm respectively).

In addition, low angular resolution VLA observations at 3.6 cm in the D configuration toward G12 were made on 2005 April 03. As before, two 50 MHz bands were observed, each one including both right and left circular polarizations. The flux and phase calibrators were 3C 286 (5.23 Jy) and J1832–105 (1.28 Jy), respectively.

The calibration and imaging for both high and low angular resolution observations were following standard procedures in AIPS. Self-calibration in phase only, and Multi-Resolution Cleaning were performed for the low angular resolution data.

2.2.2. \(\text{NH}_3\) and \(^{13}\text{CS}(1-0)\) Emission

Observations of \(\text{NH}_3\) were made with the VLA in its DnC configuration on 2004 June 06. Both transitions (2,2) and (4,4), with rest frequencies of 23722.631 and 24139.417 MHz, respectively, were observed. In order to include the main line and one pair of hyperfine satellites, the spectral line correlator was split into two overlapping bands of 64 channels each, centered at 2.30 and 0.76 MHz higher and lower than the expected line frequency for (2,2) and 1.06 and 1.24 MHz for (4,4). The Doppler tracking center velocity was set to 24 km s\(^{-1}\) (\(V_{\text{LSR}}\)) and the total velocity coverage was 94 km s\(^{-1}\), obtaining a frequency resolution of 97.656 kHz (1.25 km s\(^{-1}\)). The flux, phase and bandpass calibrators were 3C 286 (2.6 Jy), J1820–254 (0.53 Jy) and J1924–292 (9.1 Jy), respectively. Calibration and data reduction were done following standard line procedures in AIPS. All images were obtained using the task IMAGR with ROBUST = 0, while the spectra were obtained with task ISPEC after combining the two overlapping bands into a single 71 channel cube; the cube moment maps were made using the task XMOM. Gaussian fits to the observed spectra were made using the CLASS software package.

\(^8\)The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.

During the same run, \(^{13}\text{CS}(1-0)\) observations at the rest frequency of 46.24757 GHz, were also carried out. A central bandpass velocity of 24 km s\(^{-1}\) was used. Flux, phase and bandpass calibrators were the same as for \(\text{NH}_3\), as well as the calibration and data reduction. A natural weighting was used to generate the images.

3. OBSERVATIONAL RESULTS AND ANALYSIS

3.1. Radio Continuum Emission

The 21 cm NVSS contour map (Condon et al. 1998) superposed on the 3.6 cm low angular resolution VLA–D map in gray–scale toward G12 is shown in Figure 1a \textit{Left}. The morphologies of both emissions match at different scales in this region, and are in agreement with 21 cm observations from Kim & Koo (2001, their Figure 1g). Six continuum peaks are detected at 3.6 cm, one of which corresponds to the UC source.

The 3 mm continuum emission toward the UC source is split into two peaks (see Figure 1a \textit{Right}). They are separated by \(\approx 4'\) (0.26 pc at a distance of 13.5 kpc); one of them corresponds to the UC \(\text{H II}\) region (labeled as 1), while the other (labeled as 2) coincides with a water maser group reported by Hofner & Churchwell (1996). Due to the possible relation between these masers and the molecular clump reported by Hatchell et al. (2000), we will refer to Peak–2 as the molecular clump. The peak positions of the 3 mm continuum emission from the UC \(\text{H II}\) region and the molecular clump are reported in Table 2.

High angular resolution continuum observations at 0.7, 2, and 3.6 cm are displayed in Figure 1b. They show that the radio continuum emission is only associated with the UC \(\text{H II}\) region. Then, the observed emission at 3 mm and the lack of emission at 0.7, 2 and 3.6 cm toward the 3 mm peak–2, suggest that the 3 mm continuum emission toward the molecular clump could arise from dust rather than ionized gas. Integrated continuum flux densities of the ionized gas, rms noise, beam, and deconvolved sizes for these wavelengths are given in Table 3.

3.2. Line Emission

3.2.1. \(\text{H}4\alpha\)

The \(\text{H}4\alpha\) (\(\approx 3.3\) mm) emission is only detected toward the UC \(\text{H II}\) region; no emission is detected toward the molecular clump. The \(\text{H}4\alpha\) emission has a similar distribution as the radio continuum observed at 7 mm shown in Figure 1b.
Fig. 1. G12.21–0.10 (G12). a) Left: 21 cm NVSS map (contours) superposed on the 3.6 cm VLA D-configuration image in gray-scale (de la Fuente 2007). The NVSS beam size is 45$''$, while that of the 3.6 cm beam, shown in the lower-left corner, is 12$''$5 × 7$''$3 at P.A. = −13$^\circ$. Contours are –3, 3, 6, 12, 24, 48, 68, 96 × 3 mJy beam$^{-1}$. The gray-scale is 0.16 to 8 mJy beam$^{-1}$. These maps represent the extended emission in G12. Right: A close up view of the UC component traced by radio continuum emission at 3 mm (see § 2). Contours are at −3, 3, 9, 18, 27, 48 times RMS noise of 1.7 mJy beam$^{-1}$. The beam size is shown in the bottom left panel. The positions of the UC H II region and the molecular clump are labeled as 1 and 2 respectively. In all panels, the crosses mark the position of the water masers from Hofner & Churchwell (1996). b) Radio continuum emission at 0.7, 2, and 3.6 cm (VLA-CnB) toward G12. The contour levels correspond to −1, 1, 2, 4, 8, 16, 32, 64 × RMS noise presented in Table 3 for each wavelength. The synthesized beam for each map is shown in the lower left corner (see Table 3).

The H41α spectrum toward G12 is shown in Figure 2 (upper panel). Line emission was detected in the velocity range of ≈10 to 45 km s$^{-1}$, with a peak at about 30 km s$^{-1}$. The results of the Gaussian fit of this recombination line are presented in Table 4.

The H41α velocity, 20–25 km s$^{-1}$is similar to that of the molecular emission from $^{13}$CO(1–0), C$^{18}$S(2–1), and C$^{18}$S(3–2) both from Kim & Koo (2003) and this work (see below). In addition, the H41α LSR central velocity is in agreement with that reported by Kim & Koo (2001) using H76α for three positions in the extended emission (≈27 km s$^{-1}$ on average, see their Figure 1g). The ionized gas in G12, present at different scales (UC and extended emission; see Figure 1), coexists with the molecular gas and originates in the same star forming region.

3.2.2. $^{13}$CS(2–1)

Figure 3 shows the channel maps of the $^{13}$CS(2–1) line emission superposed on the 3.6 cm continuum emission. The deconvolved size of this molecular region is ≈ 4$''$5 × 2$''$0 (0.36 × 0.16 pc) with the major axis oriented approximately in the E–W direction, while the $^{13}$CS(2–1) peak emission observed at $V_{\text{LSR}} = 24$ km s$^{-1}$ is blueshifted (≈5 km s$^{-1}$) with respect to the H41α. The $^{13}$CS(2–1) line spectrum is shown in Figure 2 (lower panel). Observed parameters (flux densities, rms noise, beam, and deconvolved sizes) for $^{13}$CS(2–1) toward G12 are presented in Table 4.

Comparing the $^{13}$CS(2–1) line and the 3.6 cm (VLA–CnB) continuum emission, we note that the $^{13}$CS(2–1) emission is not spatially associated with the UC region in G12, but rather with the molec-

$^a$Uncertainties in the integrated flux densities are estimated to be about 5% at 3.6, 10% at 2 cm, and 20% at 7 mm. The deconvolved sizes and uncertainties in flux densities were obtained using the task IMFIT in AIPS.

Figure 2 (lower panel), shows that in addition to the $^{13}$CS(2–1) line at $V_{\text{LSR}} = 24$ km s$^{-1}$, a weaker component at 92.49284 GHz is marginally detected at $V_{\text{LSR}} = 4.5\pm0.5$ km s$^{-1}$ assuming the $^{13}$CS(2–1) rest frequency; and $\Delta V = 3.6\pm1.1$ km s$^{-1}$. A possible candidate to explain this weak emission is the molecule C$_3$S ($\nu_0 = 92.48849$ GHz; Morata et al. 2003) at $V_{\text{LSR}} = 14.1\pm0.5$ km s$^{-1}$. Although this molecular line seems to be real, given the low signal–to–noise ($\approx2.5\sigma$ at the peak), we cannot determine the physical parameters of the molecular gas from which this emission arises.

3.2.3. $^{13}$CS(1–0)

Figure 4 shows the channel maps of the $^{13}$CS(1–0) emission towards G12 superposed on the $^{13}$CS(2–1) integrated map as comparison. Although $^{13}$CS(1–0) and $^{13}$CS(2–1) present different morphologies, both are spatially associated with the molecular clump (3 mm Peak–2). This morphological difference could in part be due to the different spatial resolution achieved for each molecular line. However, the $^{13}$CS(1–0) emission presents a complex morphology as revealed by each channel map (see also the integrated emission shown in the inset of the 27.2 km s$^{-1}$ panel). This mor-
The two electric hyperfine components were fit with two Gaussians and the results of the fits are given in Table 5.

The (4,4) main peak line flux density is weaker than that measured in the (2,2) line. The observed widths of 8–9 km s\(^{-1}\) are evidence of highly supersonic turbulent motions in the molecular gas (Garay & Lizano 1999). The observed line parameters, flux densities, rms noise, beam, and deconvolved sizes for both transitions (2,2) and (4,4) are presented in Table 5. Within the uncertainties, the (2,2) and (4,4) V\(_{\text{LSR}}\) and \(\Delta V_{\text{obs}}\) are in mutual agreement. The measured LSR velocities of both transitions are slightly smaller (\(\approx 1\) km s\(^{-1}\) than those reported by Churchwell et al. (1990) and Cesaroni et al. (1992) for (2,2) and (4,4) using the Effelsberg 100 m telescope, while the \(\Delta V_{\text{obs}}\) for (2,2) and (4,4) are \(\approx 1\) km s\(^{-1}\) and \(\approx 4\) km s\(^{-1}\) greater, respectively. The line width difference indicates motion of the hotter compact (4,4) gas relative to the cooler extended (2,2) gas as discussed in Cesaroni et al. (1992).

Neither the (2,2) nor the (4,4) spectra show detectable anomalies in the satellite hyperfine components like those observed toward S106 in the NH\(_{3}\) (1,1) transition (Stutzki et al. 1982). Hence we can assume that the populations in the metastable levels are in LTE. To calculate physical parameters of the region based on the NH\(_{3}\) spectra, we also assume that true intrinsic widths, \(\Delta V_{t}\), are equal to the observed values, \(\Delta V_{\text{obs}}\).

Optical depths for the main lines, \(\tau_{\text{main}}\), of 3.5±0.5 and 8.0±0.5 for (2,2) and (4,4) transitions, respectively, were calculated numerically (Ho & Townes 1983, equation 1). The total optical depth can be calculated as \(\tau_{\text{tot}} = (1/b)\tau_{\text{main}}\) where \(b\) represents the normalized (to total intensity) relative intensities of the main line. Parameter \(b\) values of 0.8 and 0.93 for (2,2) and (4,4) respectively were assumed (Ho 1977), obtaining \(\tau_{\text{tot}}^{2,2} = 4.4±0.5\) and \(\tau_{\text{tot}}^{4,4} = 8.6±0.5\). In addition, excitation temperatures

\(^c\)The size of the source was obtained from the moment 0 image using IMFIT in AIPS.
Fig. 3. $^{13}\text{CS}(2-1)$ channel maps (contours) with channel width of 1.62 km s$^{-1}$ are shown between 16 and 29.0 km s$^{-1}$ superposed on the radio continuum emission at 3.6 cm (VLA-CnB, gray-scale) of G12. The gray-scale goes from $-1.24$ to 79.83 mJy beam$^{-1}$. Contours are at $-3, 3, 4, 5, 6, 7, 8, 9 \times 35$ mJy beam$^{-1}$ (RMS noise). The synthesized beam of the $^{13}\text{CS}(2-1)$ observations ($3''18 \times 2''51$ with a P.A. of $-43.3^\circ$) is shown in the top left panel. The crosses mark the position of water masers from Hofner & Churchwell (1996).

($T_{\text{exc}}$) of 78$\pm$5 K and 35$\pm$5 K for (2,2) and (4,4) were calculated in a standard way by solving the transfer equation (Ho 1977; Ho & Townes 1983). The column densities for (2,2) and (4,4) transitions in terms of $\tau_{\text{main}}$, $T_{\text{exc}}$ and $\Delta V_t$ were computed through the $\tau_{\text{tot}}$ definition given by Ungerechts et al. (1986) using the respective Einstein coefficient for spontaneous de-excitation; $A_{\pm}(2,2) = 2.23 \times 10^{-7}$ s$^{-1}$ and $A_{\pm}(4,4) = 2.82 \times 10^{-7}$ s$^{-1}$. Hence $N(2,2) = 2.6 \pm 1.0 \times 10^{16}$ cm$^{-2}$ and $N(4,4) = 2.0 \pm 1.0 \times 10^{16}$ cm$^{-2}$.

The rotational temperature, $T_{12} = 77 \pm 10$ K, was computed in terms of the (2,2) and (4,4) peak flux densities and velocity widths (see Table 5) considering the same solid angle for both emissions. Using this rotational temperature, a rotation level diagram for para-NH$_3$ (Walmsley & Ungerechts 1983; Poynter & Kakar 1975) considering collisional transitions between K-ladders and transitions which follow the parity transition rule, and doing the calculations in statistical equilibrium derived by Walmsley & Ungerechts (1983) with the numerical computations of Danby et al. (1988) in detailed balance, we obtained a value for the kinetic temperature of $T_k = 86 \pm 12$ K.

4. DISCUSSION

4.1. The Hot Molecular Core

The kinetic temperature (86 K), volumetric density ($1.5 \times 10^6$ cm$^{-3}$) and linear size ($\approx 0.22$ pc, assuming a distance of 13.5 kpc) generally coincide with the operational definition of HMC: hot
Fig. 4. $^{13}$CS(1–0) maps of individual velocity channels from the main line spectra of G12 (contours), superposed on the $^{13}$CS(2–1) integrated map (in gray scale). Velocities from 18.9 to 28.4 km s$^{-1}$ are shown in each map. The $^{13}$CS(1–0) integrated emission map (inset in the 27.2 km s$^{-1}$ panel) shows a complex edge-like structure morphology with three components labeled E (East), W (West), and N (North). The maximum of emission for each of these components corresponds to ≈20, 23 and 26 km s$^{-1}$ respectively. The contours are $-3, 3, 5 \times 3.6$ mJy (RMS noise). The beam size is 1$''$.44 $\times$ 1$''$.26 with a P.A. of $-79^\circ$, shown in the bottom left of the first map. The crosses mark the position of water masers from Hofner & Churchwell (1996).

($\gtrsim$ 100 K), dense ($\approx$10$^5$ to 10$^8$ cm$^{-3}$), and small (size $\lesssim$ 0.1 pc) molecular gas structures (Cesaroni et al. 1992; Garay & Lizano 1999). So, based on these characteristics, we suggest that the molecular gas clump detected in G12 is a hot molecular core (G12–HMC hereafter).

Several maps of the molecular line emission from the G12–HMC region are presented in Figure 6. No radio continuum source was detected toward the G12–HMC position (Figure 6a) where the group of H$_2$O masers is located. This could be explained following the suggestion of Walsh et al. (2003)

a Uncertainties are from Gaussian fits. The flux densities are from a box covering the HMC.

b These two velocity values correspond to satellite lines without fitting.

c Average values between the corresponding pair from the Gaussian fitting.

The NH₃(2,2) and (4,4) emission clearly coincides with the molecular clump observed at 3 mm (see Figure 1a), as well as with the group of masers. The distribution of molecular gas from both transitions, NH₃(2,2) and (4,4), is similar, although the NH₃(4,4) emission is slightly more compact than the NH₃(2,2) emission, suggesting that the hotter and denser gas is confined to a smaller-scale structure. Note that Figures 6c and 6d show the more extended and more compact emission, respectively.

The first moment map of the (2,2) transition shows a velocity gradient from E to N (following the nomenclature of the inset in Figure 4) from 21 to 28 km s⁻¹ over ≈4″ (≈30 km s⁻¹ pc⁻¹). A similar behavior is observed for the (4,4) moment–1 map (de la Fuente et al. 2010), but from 21 to 27 km s⁻¹ over ≈3″ corresponding to 25 km s⁻¹ pc⁻¹. For ¹³CS(1−0), from ≈20 to ≈26 km s⁻¹, we obtain a velocity gradient of ≈3 km s⁻¹ arcsec⁻¹ (or 45 km s⁻¹ pc⁻¹), and for the ¹³CS(2−1) emission ≈28 km s⁻¹ pc⁻¹, which is similar to that of the...
NH$_3$(2,2) map (compare the grey–scale bars in Figures 6a and 6c). The $^{13}$CS and NH$_3$ emission coincide in position and kinematics, which suggests no chemical differentiation in the HMC.

In addition to the velocity gradient from E to N for $^{13}$CS(1–0), a velocity gradient from W to N of $\approx$1.5 km s$^{-1}$ arcsec$^{-1}$ (or 23 km s$^{-1}$ pc$^{-1}$) is also estimated. A comparison of these results with those reported for Orion–IRc2 HMCs (Chandler & Wood 1997) suggests that $^{13}$CS(1–0) is a good candidate line to trace the internal structure of HMCs as observed in Figure 6d.

Assuming that the 3 mm flux density is due to warm dust, we derive a clump mass $M_{\text{clump}} = gS_{\nu}d^2 / \kappa_{\nu}B_{\nu}(T_d)$ (e.g., Beltrán et al. 2006) for the G12–HMC of $\approx 2.0 \times 10^3$ $M_\odot$, where a gas–to–dust ratio of $g = 100$ and a dust mass opacity coefficient of $\kappa_{112} = 0.2$ cm$^2$ g$^{-1}$ (Ossenkopf & Henning 1994) were adopted. A flux density of 0.15 Jy (Table 3), a distance of 13.5 kpc, and a temperature $T_d = 86$ K (Table 6) were assumed. In addition, considering a 3 mm deconvolved angular size of 1.7$\pm$0.5$, assuming that all hydrogen is in molecular form and that the clump is spher-
Fig. 7. NH$_3$(2,2) position–velocity (PV) diagram of the HMC presented as grey-scale in Figure 6a and 6b. The plots are slices in the directions X and Y shown in the lower-right corner in Figure 6b. The origin of the position axes is located at $\alpha_{2000} = 18^h12^m40^s$, $\delta_{2000} = -18^\circ24^\prime15^\prime\prime$. Contours are at $-4, 5, 6, 7, 8, 9, 10, 11 \times 1.6$ mJy beam$^{-1}$. Dashed lines mark the systemic velocity of the core at $\approx 23$ km s$^{-1}$.

In addition, the H$_2$ column density was calculated as $N$(H$_2$) = $\Theta_S$ n(H$_2$) where $\Theta_S$ is the deconvolved linear size in cm ($3''\pm0.1 = 0.22\pm0.01$ pc at 13.5 kpc; using $\Theta_S = \sqrt{\theta_x \theta_y}$ from Table 5). The relative abundance $(X_{NH_3})$ between NH$_3$ and H$_2$ was calculated as $N$(NH$_3$)/$N$(H$_2$). A molecular gas mass of the clump using ammonia, $M$(NH$_3$), was determined using equation 12 of Garay & Lizano (1999) with a radius $R = 0.11\pm0.01$ pc, giving a value of $M$(NH$_3$) = $830\pm40$ M$_\odot$.

Since the virial mass estimations ($2200$ M$_\odot$ from $^{13}$CS(2$\rightarrow$1), and $\approx 1500$ M$_\odot$ to $\approx 1800$ M$_\odot$ from NH$_3$) are about twice the ammonia gas mass ($\approx 830 \pm 40$ M$_\odot$) we conclude that the G12–HMC may not be gravitationally bound. The physical parameters of this HMC are summarized in Table 6.

4.2. HMC Internal Heating Source

From the flux density at 3 mm and the upper limit at 7 mm from the molecular clump emission ($3\sigma = 1.8$ mJy), a spectral index of $\alpha \approx 4.5$ is obtained. This value suggests that the 3 mm emission arises from optically thin dust. If we consider that the dust in the molecular clump is only heated by external radiation, a lower limit to the dust temperature can be obtained using the formulation of Scoville & Kwan (1976, equation 9), under the assumption that no absorption exists between the ionizing star of the UC H II region and the clump. Using the 3 mm integrated flux density (see Table 3) and assuming an external O6.5 ZAMS ionizing star (Kim & Koo 2001, $L_{\text{star}} \approx 1.5 \times 10^5 L_\odot$), a dust absorptivity $\kappa_\nu \propto \nu^{+2}$, and a projected separation between the clump and the ionizing star (which is presumed to be at the focus of the cometary UC H II region) of 0.26 pc (4$''$ at 13.5 kpc), we obtain $T_d = 130$ K. This temperature is slightly greater than the values obtained with other molecular tracers (see Table 1, § 3.2.4 and § 4.2). However, not all luminosity of the O6.5 ZAMS ionizing star reaches the HMC. Considering a dilution factor of $\Omega/4\pi \approx 0.06$ (where $\Omega$ is the solid angle subtended by the ammonia core as seen from the ionizing star of the UC H II ), the fraction of incident luminosity from the UC H II on the HMC would be $L_{\text{inc}} \approx 9000 L_\odot$. Using this quantity as the energy budget of the HMC, a dust temperature of about 70 K is estimated, which is similar to the kinetic temperature obtained in § 3.2.4 (86±12 K). This implies that an external heating source is not needed to explain the temperature of the core. However, the detection of water and methanol masers suggests the presence of a YSO in the HMC.
4.3. HMC Kinematics

There are different types of gas motion that can occur in HMCs, i.e., infall, rotation, and expansion/outflows. Outflows and rotation have been invoked to explain velocity gradients toward several HMCs (Cesaroni et al. 1998). In the case of rotation, flattened compact ‘disk–like’ structures with diameters greater than 0.1 pc (Garay & Lizano 1999, and references therein) are observed, and the velocity gradient may indicate the kind of rotation: differential or rigid body.

The NH$_3$(2,2) position–velocity (PV) diagrams of G12–HMC are presented in Figure 7. We find no evidence of infall (e.g., redshifted absorption features). The central parts of the G12–HMC present larger velocity widths compared to the edges ($\approx$6 versus 2 km s$^{-1}$), and the overall structure of the HMC is elongated. The rotation scenario is possible.

The velocity widths across the HMC in the PV diagrams are also consistent with expansion motions. Two components on each side of the HMC central position (systemic velocity of $\approx$23 km s$^{-1}$), have velocities of $\approx$26 km s$^{-1}$ and $\approx$20 km s$^{-1}$, suggesting that G12–HMC could be a structure with expansion motions at velocities of a few km s$^{-1}$ in the SE–NW direction.

We have obtained images of integrated velocities from $\approx$30 to 23 km s$^{-1}$ and from 23 to 18 km s$^{-1}$ using only the main line, and we do not see a clear spatial separation between this red–shifted and blue–shifted components. The opposite was found in the high–mass star forming regions G25.65+1.05 and G240.31+0.07, where high velocity molecular gas is associated with bipolar outflows (Shepherd & Churchwell 1996). Higher angular resolution observations are needed to confirm the rotation hypothesis and whether an outflow is present in the core.

5. SUMMARY AND CONCLUSIONS

We present observations of radio continuum (0.3, 0.7, 2 and 3.6 cm) and spectral lines (H41$\alpha$, $^{13}$CS(2–1) and (1–0), NH$_3$(2,2) and (4,4)) toward the cometary H II region G12.21–0.10. Continuum emission is detected at all wavelengths toward the UC H II region. We also find 3 mm continuum emission toward a molecular clump located about 4$''$ from the UC H II region. $^{13}$CS and NH$_3$ emission is only detected toward the molecular clump and we do not find any chemical differentiation between these species.

We find evidence that the molecular clump is consistent with a hot (86 K), dense ($1.5\times10^6$ cm$^{-3}$), large (0.22 pc), and turbulent ($\Delta V_{obs} \approx 8$ km s$^{-1}$) molecular core. We also find that this hot molecular core shows a marginal velocity gradient in the SE–NW direction. Given that the HMC coincides with a water and methanol maser group, we speculate that a YSO, not detected in the centimeter radio continuum, could be forming inside the HMC.

Finally, we find that $^{13}$CS and NH$_3$ are good candidates to trace the internal structure of HMCs. However, high angular resolution and higher sensitivity observations are needed to fully characterize this HMC.

The authors thank the anonymous referee for useful comments which improved this work. E. F. very gratefully acknowledges financial support from CONACYT (grant 124449, SNI III 1326 México), PROMEP/103.5/08/4722, and facilities from NRAO, NMT, IRyA–UNAM, INAOE. He also acknowledges Benemérita Universidad Autónoma de Puebla (BUAP); Arturo Fernández and Humberto Salazar, for support during a research stay on December, 2017. We would like to thank Laurent Loinard, Mayra Osorio, Guillem Anglada, Jana Benda, Simon Kemp, Susana Lizano, and Luis Felipe Rodríguez for useful discussions. We also thank Gilberto Zavala, Miguel Espejel, Alfonso Ginori and Andrés Rodríguez (IAM–UdeG) for computer support. P. H. acknowledges partial support from NSF grant AST-0908901 for this project.
