

## Fe II FLUORESCENCE IN SYMBIOTIC STARS

M. Eriksson,<sup>1,2</sup> H. Veenhuizen,<sup>2</sup> G. M. Wahlgren,<sup>1</sup> and S. Johansson<sup>1</sup>

### RESUMEN

Se ha investigado la fluorescencia por PAR del ion Fe II en ocho estrellas simbióticas con muy diversos valores de la temperatura de la componente caliente y del período orbital. Los datos empleados son espectros de archivo del IUE. Todas las líneas de bombeo estudiadas se encuentran en la región (1200-2000 Å) del IUE, excepto He II  $\lambda$ 1084.942 y O VI  $\lambda$ 1032.041. Las líneas de fluorescencia del Fe II están principalmente en la región Fe II, pero algunas caen en la región de las líneas de bombeo. Nuestro objetivo es entender las condiciones óptimas para la formación de líneas de fluorescencia por PAR del Fe II. Tres de los sistemas estudiados, RR Tel, AG Peg and V1016 Cyg, presentan 10-30 canales activos del Fe II. Dos condiciones relacionan a estos sistemas. La componente caliente es una enana blanca de temperatura extrema ( $80 \cdot 10^3$ - $150 \cdot 10^3$  K), y los tres sistemas son novae simbióticas, que han tenido erupciones en los últimos 150 años. Los sistemas AG Dra, RW Hya and R Aqr tienen sólo 2-3 canales activos del Fe II. Los dos sistemas restantes, CI Cyg and T CrB, no mostraron líneas de fluorescencia del Fe II. Estos sistemas tienen en común que la intensidad de emisión de los elementos altamente ionizados es menor que en la mayoría de los sistemas simbióticos, y que la componente caliente puede ser una estrella de secuencia principal con acreción, en vez de una enana blanca.

### ABSTRACT

Fe II fluorescence by PAR has been investigated in eight symbiotic stars having a wide range in temperature of the hot component and orbital period. The data used are spectra obtained from the IUE archive. All pumping lines investigated in this work are in the short wavelength region of IUE (1200-2000 Å), except for He II  $\lambda$ 1084.942 and O VI  $\lambda$ 1032.041. The resulting Fe II fluorescence lines are mainly in the long wavelength region (2000-3300 Å), but a few fall in the same region as the pumping lines. The aim is to understand the optimal conditions for formation of Fe II fluorescence lines caused by PAR. Three of the selected systems, RR Tel, AG Peg and V1016 Cyg, have 10-30 active Fe II channels. Two conditions connect those systems to each other: The hot component is a white dwarf of extreme temperature ( $80 \cdot 10^3$ - $150 \cdot 10^3$  K) and all three systems are so called symbiotic novae and have had outbursts during the last 150 years. Three systems, AG Dra, RW Hya and R Aqr, have only 2-3 active Fe II channels. In the two remaining systems, CI Cyg and T CrB, Fe II fluorescence lines were totally absent. These two systems have two features in common: The emission strength of highly ionized elements is less than in most symbiotic systems, and the hot component is suspected to be an accreting main sequence star rather than a white dwarf.

*Key Words:* **ATOMIC PROCESSES — BINARIES: SYMBIOTIC**

### 1. INTRODUCTION

Symbiotic stars are a subgroup of interacting binaries, and consist of a red giant, a hot UV source and a surrounding nebula. The orbital period of such a system is typically a few years, and the hot source (usually a white dwarf) is accreting material, either from the red giant wind, or by mass transfer caused by Roche lobe overflow from the red giant in some systems. This leads to accretion discs and sometimes even jets (Kafatos et al. 1987). Between the two stars there is a mechanically heated region caused by

the collision of the winds from the two components (Mürset, Wolff & Jordan 1997). A few of the symbiotic stars have had nova-like outbursts, followed by a slow decline lasting decades, and are referred to as symbiotic novae. This complexity leads to regions with very different temperatures and ionization stages, which increases the probability of PAR (Photoexcitation by Accidental Resonance) processes being observed. The most famous PAR process is the Bowen mechanism (Bowen 1935). In the symbiotic stars RR Tel and V1016 Cyg ten Fe II lines from high energy levels were explained as being pumped by PAR through the channel  $a^4F_{9/2} - y^4H_{11/2}$  at 1548.204 Å by the CIV  $\lambda$ 1548.187 line (Johansson 1983). Eriksson, Johansson & Wahlgren (2001)

demonstrated that this PAR channel was active in six additional symbiotic stars: AG Peg, EG And, SY Mus, RX Pup, RW Hya and Z And. The Fe II UV emission lines of RR Tel and AG Peg have been analyzed (Hartman & Johansson 2001; Eriksson, Johansson & Wahlgren 2003), revealing 27 pumped Fe II channels in RR Tel and 30 in AG Peg with 120 and 180 Fe II fluorescence lines, respectively. PAR is hence not a rare phenomenon but a dominant characteristic for the UV spectra of these two stars.

In this work the UV emission line spectra of RR Tel and AG Peg, along with six additional symbiotic systems, CI Cyg, V1016 Cyg, RW Hya, AG Dra, R Aqr and T CrB, were analyzed. The aim is to learn if Fe II pumping by PAR is common in symbiotic systems or if the numerous active Fe II channels make a special case for only a few systems. By comparing the results of the different symbiotic stars we also hope to see what conditions are ideal for PAR in symbiotic systems.

## 2. FE II LEVELS PUMPED BY HIGHLY IONIZED ELEMENTS.

At short wavelengths (1000 - 2000 Å) most of the strong lines originate from more ionized elements (Fig 1). These lines are most probably formed either in the hot wind from the white dwarf or in regions of the system ionized by the UV radiation from the white dwarf. If such a region irradiates a Fe II region the Fe<sup>+</sup> ions can start to fluoresce by PAR mechanisms.

Fe II levels pumped by highly ionized elements were observed in six of the eight selected systems and 23 different pumping channels were observed.

TABLE 1

FE II LEVELS PUMPED BY LINES FROM HIGHLY IONIZED ELEMENTS

Pumping line	Pumped level	$\lambda_{ch}^a$ (Å)
Si III] $\lambda$ 1892.030	$z^4G_{9/2}$	1892.078

<sup>a</sup>Wavelength of the Fe II channel.

The pumped levels are listed with their corresponding pumping line in Table 1.

## 3. FE II LEVELS PUMPED BY H I $\lambda$ 1215.671

The H Ly $\alpha$  line is strong and broad in cool giant stars where it has been observed to pump Fe II to high odd levels (Johansson & Jordan 1984). In symbiotic systems the Lyman emission originates from the cool red giant atmosphere and not from the hot regions responsible for the Fe II fluorescence discussed in the previous section.

Among the eight selected symbiotic stars numerous H Ly $\alpha$  pumped Fe II levels were observed (Table 2). Atomic physics details are given in the study of RR Tel by Hartman & Johansson (2000). Three systems, RR Tel, AG Peg and V1016 Cyg, have spectra showing lines originating from such levels. All three of these systems have had a nova outburst during the last 150 years. Since none of the other five

<sup>a</sup>Stars showing fluorescence lines: R=RR Tel, A=AG Peg and V=V1016 Cyg.

symbiotic systems showed any sign of H Ly $\alpha$  pumped Fe II levels, it seems as if an outburst changes the properties of the circumstellar environment so that H Ly $\alpha$  can reach the Fe II region.

#### 4. STARS WITH NUMEROUS FE II FLUORESCENCE LINES

Three systems showed substantial Fe II fluorescence (Fig 2): RR Tel (120 Fe II fluorescence lines), AG Peg (180 lines) and V1016 Cyg (58 lines). The temperature of the white dwarfs of V1016 Cyg and RR Tel is extremely high,  $\sim 145000$  K for V1016 Cyg (Mürset & Nussbaumer 1994) and  $\sim 142000$  K for RR Tel (Jordan, Mürset & Warner 1993). The temperature of the white dwarf in AG Peg is  $\sim 86000$  K (Altamore & Cassatella 1997), which is more common for symbiotic stars. Orbital periods for the systems are very different:  $\sim 2$  years for AG Peg and  $\sim 9$  years for V1016 Cyg (Meier et al. 1994). However, these three systems all belong to the subclass of symbiotic novae, which is a class of symbiotic stars that have undergone slow nova outbursts. The outburst started in 1850 for AG Peg, in 1944 for RR Tel and in 1964 for V1016 Cyg.

#### 5. STARS WITH FEW FE II FLUORESCENCE LINES

The five systems not classified as symbiotic novae have much fewer Fe II fluorescence lines. Only three of them had Fe II fluorescence lines at all, RW Hya (12 lines), R Aqr (6 lines) and AG Dra (5 lines). In RW Hya and AG Dra the only line pumping Fe II is C IV  $\lambda 1548.187$  while Si III]  $\lambda 1892.030$  and O III]

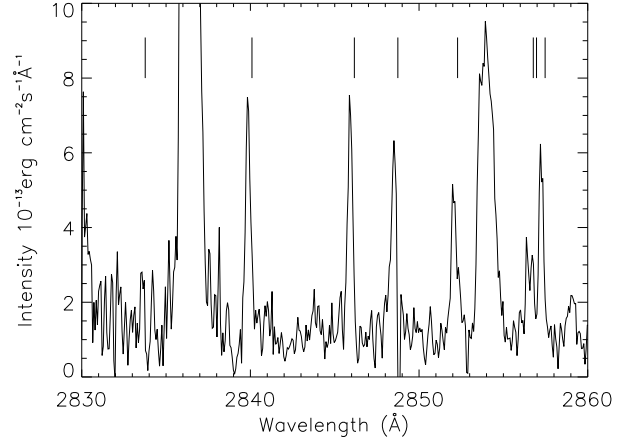

Fig. 2. High resolution IUE spectrum number LWP04961 of V1016 Cyg. All marked lines are Fe II fluorescence lines.

$\lambda 1666.150$  cause the Fe II fluorescence in R Aqr. The white dwarf temperature of RW Hya,  $\sim 41000$  K (Sion et al. 2002), and R Aqr,  $\sim 61000$  K (Meier & Kafatos 1995), is low compared to the stars with many Fe II fluorescence lines. This indicates that the temperature of the white dwarf is important for PAR processes in symbiotic systems. However, the white dwarf in AG Dra has a temperature of  $\sim 110000$  K (González-Riestra et al. 1999) and does still have only a few Fe II lines.

#### 6. STARS WITH NO FE II FLUORESCENCE

Two symbiotic systems, CI Cyg and T CrB, do not show any sign of Fe II fluorescence. The hotter component in T CrB is suggested to be a main sequence star (Kenyon & Garcia 1986), which accretes  $\sim 10^{-6} M_{\odot}$  per year from the cooler component leading to  $T_{eff} \sim 25000$  K in the disc. This can explain the absence of Fe II fluorescence in T CrB since the UV flux from the hot component would probably not create large amounts of  $C^{3+}$ ,  $Si^{2+}$ , or  $N^{4+}$ . T CrB is the most compact system among the eight selected symbiotic stars with a period of only 227.5 days. Even if the hotter component is a white dwarf, the UV flux from the hot component may not reach very far since it can be obscured by material expelled from the red giant. Also CI Cyg is suggested to have a hot component in the form of an accretion disc around a main sequence star (Iijima 1982). Thus, the UV flux of the hot component depends on the accretion rate from the red giant onto the disc. Kenyon et al. (1991) measured a mass transfer of a few times  $10^{-5} M_{\odot}$  per year onto the disc. Hence, the absence of Fe II fluorescence lines in the spectrum of CI Cyg can also depend on deficient UV flux in the system.

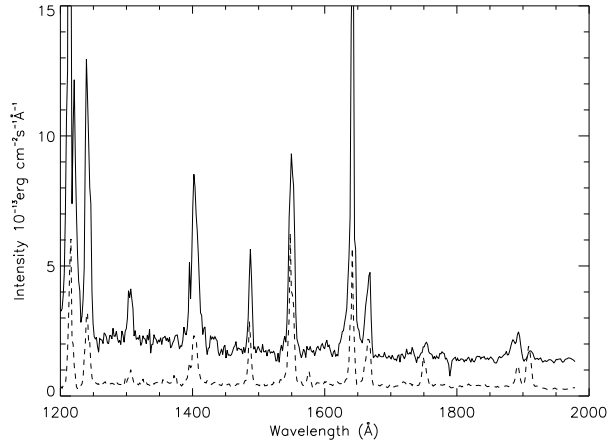

Fig. 3. Comparison between emission strength of highly ionized elements in AG Dra and CI Cyg. The solid line corresponds to the low resolution spectrum swp09084 of AG Dra and the dotted line to the low resolution spectrum swp36320 of CI Cyg. Notice also the difference in the UV continuum.

Both CI Cyg and T CrB have much weaker emission lines between 1200-2000 Å from the highly ionized elements (Fig 3). This supports the idea of less ionizing UV flux leading to fewer regions of elements that can pump Fe II.

## 7. SUMMARY

The symbiotic stars in our selection can clearly be placed in three different groups with respect to Fe II fluorescence (Table 3):

- Symbiotic novae with white dwarfs of extremely high temperature.
- Symbiotic systems with white dwarfs of moderate temperature (AG Dra causes a problem because of the high temperature of the white dwarf).
- Symbiotic systems with an accreting main sequence star instead of a white dwarf.

Two conclusions can probably be drawn. Fe II fluorescence increases after a nova outburst and a white dwarf is needed in the system to obtain UV radiation enough to create regions of elements that can pump Fe II. However, to confirm the statements a larger number of stars have to be included in the analysis. It would also be of value to investigate whether the pumping of other elements such as Co II and O III, known to be pumped by PAR in symbiotic stars, follow the same trends as Fe II.

## DISCUSSION

*Kaper* – Did you correlate the properties of the Fe II fluorescence lines with those of Raman scattered emission lines, as observed in these systems by Vogel, Nussbaumer et al.?

*Eriksson* – No. Raman scattered lines are much broader because of short lifetimes in associated virtual states. I suppose that environments positive for PAR also could be in favor of Raman scattering. If I remember correctly, Raman scattering was observed in the same systems where we found many Fe II pumping channels.
