FERO (FINDING EXTREME RELATIVISTIC OBJECTS): STATISTICS OF RELATIVISTIC BROAD FE K\textalpha LINES IN AGN

A. L. Longinotti,\textsuperscript{1} I. de La Calle,\textsuperscript{1,2} S. Bianchi,\textsuperscript{3} M. Guainazzi,\textsuperscript{1} and M. Dovciak\textsuperscript{4}

RESUMEN

Las propiedades de las líneas de emisión Fe K\textalpha ensanchadas relativisticamente en núcleos activos de galaxias (AGN) son aún materia de debate en la comunidad. Los trabajos recientes parecen excluir que la línea ancha de Fe es un rasgo común en los AGN. Se presenta el análisis de una gran muestra de 157 observaciones de archivo del XMM-Newton de AGN radio callados. Este trabajo en curso es lo desarrollado desde lo reportado en Guainazzi et al. (2006).

ABSTRACT

The properties of the relativistically broadened Fe K\textalpha line emitted in Active Galactic Nuclei (AGN) are still debated among the AGN community. Recent works seem to exclude that the broad Fe line is a common feature of AGN. The analysis of a large sample composed by 157 XMM-Newton archival observations of radio quiet AGN is presented here. This ongoing project is a development of the work reported in Guainazzi et al. (2006).

Key Words: galaxies: active — line: profiles — X-rays: galaxies

1. INTRODUCTION

The detection of a broadened and skewed Fe K\textalpha line in AGN spectra is generally interpreted as an effect on X-ray photons due to the gravitational field of the black hole. Measuring the parameters of broad Fe lines provides therefore a diagnostic of the accretion disc structure and of the central object (see Fabian & Miniutti 2005 for a review). Many publications on individual sources observed by the high throughput X-ray satellite XMM-Newton invoke the presence of a relativistic disc Fe line (e.g. Wilms et al. 2001; Fabian et al. 2002; Longinotti et al. 2003). Recent works on large samples of AGN converged to say that the broad line is more common in low luminosity AGN (Nandra et al. 1997, 2007; Strebyanska et al. 2005; Jimenez-Bailón et al. 2005; Guainazzi et al. 2006). Nonetheless, there is no agreement on the line parameters such as its intensity and equivalent width (EW). Using a collection of 107 AGN from the XMM-Newton archive, Guainazzi et al. (2006) found a detection fraction of relativistic Fe line of 25%. The mean EW was inferred to be \sim 200 eV and the strongest lines were found in the sources with low 2–10 keV luminosity.

2. THIS WORK: PRELIMINARY RESULTS

We have expanded the work by Guainazzi et al. (2006) by refining the baseline model and including more sources. The final sample is made by 157 type 1 radio-quiet AGN with $N_H < 10^{22.5} \text{ cm}^{-2}$ (see Bianchi et al. 2007 for more details on the sample). The assumed baseline model is made by the following spectral components: primary X-ray power law, Compton reflection originated in the torus, 4 narrow emission lines with fixed energies corresponding to K\textalpha transitions from Fe I, XXV, XXVI and K\beta from Fe I. A Gaussian line of 50 eV width is included to fit the Compton Shoulder. The intensities of the Fe K\beta and of the Compton Shoulder are tied to the Fe K\alpha flux. Absorption from ionized gas is also included to take into account any spectral curvature at 6–7 keV which may be induced by warm absorbing gas along the line of sight as for NGC 3783 (Reeves et al. 2004). The klyline model (Dovciak et al. 2004) was adopted for fitting the relativistic disc line. The presence of an (additional) reflection component arising from the disc and thus gravitationally blurred, was extensively tested but it could not be distinguished from the torus reflection due to the limited XMM-Newton bandpass. A single reflection component is included in the final baseline model. When considering the whole sample, the broad line detection fraction is found to be of the order of 10% for a significance threshold of 5\sigma (Figure 1). However, a flux-limited ($F_{2–10} > 1.8 \times 10^{-11} \text{ ergs cm}^{-2} \text{ s}^{-1}$) sub-sample of 22 sources has been defined with the
The ratio plots employed in the stacking were obtained assuming the continuum (with no emission features) as a baseline model. Figure 3a shows the stacked plots for all the sources with upper limits. The prominent peak at 6.4 keV is produced by the narrow Fe Kα and the residuals at 6.5–7.2 keV are likely to be due to the contribution of ionized Fe lines and possibly of Fe Kβ. There is no significant evidence for a broad line profile in the stacked spectra ratio, the data points below 6.4 keV are statistically consistent with the fitted continuum model. Nonetheless, this ratio was obtained by “mixing” sources with different X-ray luminosities. To disentangle this effect the sources have been splitted in 3 luminosity groups (almost) equally populated. By comparing the profile of the stacked ratios to the theoretical broad line profile (blue curve in the plots), it can be concluded as a qualitative estimate that the line intensity never gets higher than 50 eV and it seems to faint with increasing luminosity. More details will be presented in a forthcoming paper (Longinotti et al. in prep.).
